Abstract. The increased sensitivity of spectral domain optical coherence tomography (OCT) has driven the development of a new generation of technologies in OCT, including rapidly tunable, broad bandwidth swept laser sources and spectral domain OCT interferometer topologies. In this work, the operation of a turnkey 1300-nm swept laser source is demonstrated. This source has a fiber ring cavity with a semiconductor optical amplifier gain medium. Intracavity mode selection is achieved with an in-fiber tunable fiber Fabry-Perot filter. A novel optoelectronic technique that allows for even sampling of the swept source OCT signal in $k$ space also is described. A differential swept source OCT system is presented, and images of in vivo human cornea and skin are presented. Lastly, the effects of analog-to-digital converter aliasing on image quality in swept source OCT are discussed. © 2005 Society of Photo-Optical Instrumentation Engineers. [DOI: 10.1117/1.1961474]

Keywords: optical coherence tomography; medical imaging; biological imaging; tunable lasers; ophthalmic imaging; skin imaging.

In 1995, Fercher et al. proposed the use of spectral domain interferometric techniques for the generation of depth-resolved reflectivity profiles (i.e., A scans) in scattering tissues. Two spectral domain techniques were presented. The first technique, which we call Fourier domain OCT, uses a broadband light source and collects the spectrally resolved interference signal in a detector-arm dispersive spectrometer. The second, which we call swept source (SS) OCT, time encodes spectral information by sweeping a narrow linewidth laser through a broad optical bandwidth. As in time domain OCT, swept source OCT uses a single photodiode detector. The detector responses for swept source and Fourier domain OCT are Eqs. (2) and (3), respectively:

$$i_{ssoct}(k) \approx \sqrt{R_R R_S} \int_{-\pi}^{\pi} S(k) \cos(2k\Delta k)dk, \quad (2)$$

$$q_{ssoct}(k) \approx \sqrt{R_R R_S} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} S(k) \cos(2k\Delta k)dkdt. \quad (3)$$

The swept source OCT signal $i_{ssoct}(k)$ is a photocurrent integrated over the linewidth of the swept laser source, while the Fourier domain OCT signal $q_{ssoct}(k)$ is the quantity of photocarriers collected over the duration of an A scan in a charge accumulation detector such as a charge-coupled device or photodiode array.

Although the initial work by Fercher et al. described the fundamental physical similarities between Fourier domain and swept source OCT, the sensitivities of spectral domain OCT...
compared to time domain OCT remained an open issue. In 1998, Andretzky et al.\(^3\) derived an expression for the sensitivity of Fourier domain OCT that showed its theoretical superior sensitivity to time domain OCT. This expression was later independently rederived and experimentally verified in 1999 by Mitsut\(^5\) and in 2003 by Leitgeb, Hitzenberger, and Fercher,\(^7\) and de Boer.\(^6\) These works, however, overlooked the underlying similarities between swept source and Fourier domain OCT that Fercher et al. recognized. These similarities were exploited by Choma et al.\(^7\) to provide a unified theoretical and experimental sensitivity analysis of all spectral domain OCT techniques that demonstrates the general sensitivity advantage of spectral domain OCT over time domain OCT. This analysis is summarized by two key points. First, the shot noise-limited signal-to-noise ratio (SNR) of an individual spectral domain pixel is given by

\[
\text{SNR}(k_n) = \frac{\rho}{e} P_S(k_n) R_S \Delta t, \tag{4}
\]

where \(k_n\) is the \(n\)th wavenumber measured \((n \in [1, N])\), \(P_S(k_n)\) is the sample power at \(k_n\), \(R_S\) is the sample reflectivity, \(\Delta t\) is the A-scan time, \(\rho\) is the detector responsivity, and \(e\) is the electronic charge. It should be noted that each SNR \(\text{SNR}(k_n)\) is comparable to the standard time domain SNR expression given by Swanson et al.\(^8\) The second key point is that, while signal adds coherently during Fourier transformation from the spectral to the time domain, noise adds incoherently. This leads to a sensitivity advantage of spectral domain OCT on the order of \(N^{-1/2}\) to \(N^{-1}\) (Fig. 1). The SNR of spectral domain OCT is thus:

\[
\text{SNR}_{\text{solar}} = \frac{\rho}{2e} P_S R_S \Delta t, \tag{5}
\]

where \(P_S\) is the total power incident on the sample.

One of the impediments to the development of robust swept source OCT systems has been the availability of stable, rapidly tunable swept laser sources. Previously swept sources have included grating\(^9\) and prism\(^10\) tuned external cavity lasers and current tuning of a laser diode.\(^11\) Recently, we\(^7\) and others\(^12\) have demonstrated a rapidly tunable swept laser source that employs a fiber ring laser configuration with an intracavity wavelength tuning mechanism. This general cavity configuration was first demonstrated in the mid-1990s,\(^13–15\) and commercial devices with an erbium-doped fiber ring that use the fiber Fabry Perot tuning mechanism shown in this work have been commercially deployed.\(^16\) We describe the design and operation of a 1300-nm swept source OCT system based on a modified version of this commercially available swept laser source. We demonstrate a novel optoelectronic wavenumber linearization technique that eliminates the need for resampling spectral domain data in software. We show high-quality SS-OCT images of the cornea and anterior segment, and discuss aliasing as a source of image artifact in spectral domain OCT.

2 Swept Source OCT System Design

A schematic of the novel all-fiber swept laser source is shown in Fig. 2. The fiber ring cavity has two important elements. First, the gain medium is a semiconductor optical amplifier (SOA) that achieves population inversion via current pumping. We used a standard polarization-insensitive SOA from InPhenix, Inc. (Livermore, California) (peak wavelength of \(\sim 1300\) nm, small signal gain of \(\sim 20\) dB, a polarization dependent ratio of \(\sim 0.9\) dB, and a saturation power of \(\sim 10\) dBm). Second, addressable wavelength (mode) selection is achieved with a fiber Fabry-Perot tunable filter (FFP-TF), a completely in-fiber device with a \(< 2\)-dB insertion loss. The FFP-TF is an all-fiber device having a cavity formed by two dielectric mirrors deposited directly onto fiber ends. A thin air-gap within the cavity is used for wavelength tuning and
control by a piezoelectric actuator with positioning resolution of atomic dimensions. The key to the stable, high-performance characteristics of the FFP-TF is the incorporation of an intrinsic beam shaping mechanism that provides intracavity waveguiding, elimination of extraneous cavity modes, and ease of mirror alignment required for high-finesse and low-loss operation. The high-performance parameters and features attained with the FFP-TFs in the 1.3–1.5-μm spectral range include wide FSR (43,000 GHz), high finesse (>10,000), low loss (<3 dB), high contrast (>70 dB), robust signal tracking and locking capability, smooth and continuous tuning, conformance to the theoretical Airy function, and compact and rugged design. For this experiment the filter parameters include a free spectral range of 190 nm, a finesse of ∼2500, a 3-dB bandwidth of ∼46 pm, and a loss of ∼1 dB. The FFP-TF is actuated by a piezoelectric element that changes the passband of the FFP-TF by lengthening or shortening the FFP-TF. This intracavity FFP-TF has a free spectral range that exceeds the gain medium bandwidth. The stacked piezo actuator (PZT) operates in a low voltage range (<150 V) and requires only ∼10 V to tune over the entire free spectral range. Numerous FFP-TFs from Micron Optics, Inc. (Atlanta, Georgia) have been deployed in optical communications over a decade, and the PZT durability is expected to be robust under present operation. The finesse of the FFP-TF allows tens of cavity modes to simultaneously lase within the ∼0.01-nm static linewidth of the laser output. The piezoelectric element in the FFP-TF is driven with a 250-Hz triangle wave, which generates a forward and backward sweep. The swept laser source power as a function of wavelength and sweep direction is shown in Fig. 3. During the forward sweep, an increasing voltage ramp is applied to the piezoelectric element, which sweeps the source output from shorter to longer wavelengths. During the backward sweep, a decreasing voltage ramp is applied to the piezoelectric element, which sweeps the source output from longer to shorter wavelengths (Fig. 3). This laser achieves a 130-nm sweep range centered at 1300 nm, ∼3 mW of output power, and full-width half-maximum bandwidth of ∼90 nm. It should be noted that the source output is different on the forward and backward sweep. This is caused by a frequency downshift in the SOA, which is believed to be due to intraband four-wave mixing via carrier-density modulation in the SOA.17–19 Only the higher-intensity forward sweep was used for imaging. We have demonstrated that the sweep rate is scalable into the kilohertz regime.20

To achieve maximal SNR and axial imaging resolution, the digitally sampled SS-OCT data must be evenly spaced in the k domain before Fourier transformation into an A scan. We have implemented an optoelectronic method that eliminates the need for the computationally intense software resampling needed in Fourier domain OCT. A small portion of the laser output is fed into a fixed fiber Fabry Perot interferometer (FPPI) with a free spectral range Δk = 372 radians/m (17.8 GHz). The output of this FPPI is monitored with a photodiode. Every time the laser sweeps through Δk, the photodiode output spikes.21 Since these spikes are evenly spaced in wavenumber, this signal was processed in analog electronics for use of the pixel clock for analog-to-digital conversion of the interferometric signal.

Since Δk is broader than the linewidth of the laser, Δk determines the maximum scan depth x_{max}

\[ x_{\text{max}} = \frac{1}{4\Delta k}. \]  

The nominal noise equivalent bandwidth (NEB) of the SS-OCT system is thus

\[ \text{NEB} = \frac{2x_{\text{max}}\Delta \lambda}{\lambda_{\text{o}}}f_{\text{ascan}} = \frac{\Delta \lambda}{2\Delta k}f_{\text{ascan}}, \]  

where \( \lambda_{\text{o}} \) is the center wavelength, \( \Delta \lambda \) is the laser sweep bandwidth, \( \Delta k \) is \( \Delta \lambda \) expressed in wavelengths, and \( f_{\text{ascan}} \) is the A-scan line rate. Due to nonlinearities in the wavenumber scan, the actual NEB will be greater than that given by Eq. (7). In other words, since the FFPI-based trigger forces even sampling in wavenumber, it necessarily forces uneven sampling in time when the source wavenumber sweep is nonlinear. Since the NEB is inversely proportional to the analog-to-digital sampling interval, nonlinear sampling in time increases the NEB due to the presence of sampling intervals shorter than those assumed in Eqs. (6) and (7). This broadening degrades the system SNR, and is analogous to the broadening observed when a sinusoidal resonant scanner is used in a rapid scanning optical delay line in a time domain OCT system.22

Our system schematic is shown in Fig. 4. The interferometer employs dual-balanced detection,23 which allows for the hardware removal of noninterferometric and autocorrelation terms. Dual-balanced detection extinguishes tens of decibels of autocorrelation and source spectral shape terms. Unfortunately, the fiber optic couplers used by us and others are not achromatic. As a consequence, the coupler splitting ratio is a function of wavelength, which renders complete extinction of autocorrection and source spectral terms not possible by dual balancing alone. The measured system sensitivity was 119 dB as measured with a −57-dB reflector. The sensitivity is ar-
rived at by adding the reflectivity of the sample reflector (in decibels) to the dynamic range (in decibels). The dynamic range in decibels was calculated as 20 times the base-10 logarithm of the ratio of the A-scan peak height to the standard deviation of the noise floor. The noise floor standard deviation was taken at the location of the A-scan peak by blocking the sample arm. The measured sensitivity compares well with the theoretical SNR of 121 dB ($\rho=0.9$, $P_0=0.36$ mW, and $\Delta t = 1.25$ ms). With $\Delta x=0.1$ mm, the imaging scan depth was 4.2 mm. The measured coherence length (i.e., axial resolution) was 9.1 $\mu$m (6.5 $\mu$m) in air (tissue), which compared favorably with a predicted coherence length of 9 $\mu$m in air. Importantly, the coherence length remained constant throughout the entire 4.2-mm scan depth (Fig. 5). Further, the amplitude falloff at 4.2 mm was $\sim 3$ dB owing to the antialiasing filter. Each x-domain A scan contains 649 points.

3 In Vivo Swept Source OCT Imaging

OCT imaging of the cornea and anterior segment of the eye has important potential applications in glaucoma evaluation and refractive surgery (e.g., LASIK).\textsuperscript{24} Compared to ultrasound biomicroscopy, OCT is noncontact and achieves higher spatial resolutions.\textsuperscript{32} In terms of imaging the anterior chamber angle with gonioscopy,\textsuperscript{25} it has the advantage of being able to visualize structures behind the iris. OCT also has the potential to evaluate in detail the response of the angle structures to light an accommodation, which is an important part of the glaucoma workup. The 1300-nm window is particularly well suited for imaging these anatomical regions because, compared to the 800-nm window, it has deeper penetration into scattering tissue and less penetration into the vitreous. To this end we performed in vivo imaging of the human cornea and anterior segment using slit-lamp biomicroscope adapted optics. Details of this setup are in Patil et al.\textsuperscript{24} The image in Fig. 6 contains 300 A scans. Major anatomic features were visualized, including the iris stroma, iris pigment epithelium, ciliary body, angle of anterior chamber, aqueous, corneal stroma, sclera, and scleral spur. The corneal epithelium was visualized in Fig. 7.

OCT imaging of the skin is an emerging technology for subsurface assessment of structure, collagen birefringence, and blood flow.\textsuperscript{26} Its resolution is superior to that of ultrasound biomicroscopy.\textsuperscript{27} Morphologic changes such as blistering and inflammatory changes such as psoriasis have been...
Aliasing artifact arises because autocorrelation and source spectral shape terms are centered around \( x = 0 \). A third source of ambiguity arises when spectral domain fringes from depths greater than \( x_{\text{max}} \) are aliased down to depths less than \( x_{\text{max}} \) (Fig. 7). The apparent or aliased depth of an object \( x_{a} \) is given by:

\[
x_{a} = \begin{cases} 
\text{mod}(x, 2x_{\text{max}}) & \text{if } \text{mod}(x, 2x_{\text{max}}) \leq x_{\text{max}} \\
-x_{\text{max}} - \text{mod}(x, 2x_{\text{max}}) & \text{if } \text{mod}(x, 2x_{\text{max}}) > x_{\text{max}}
\end{cases}
\]

(8)

where \( \text{mod}(a, b) \) yields \( a \) modulo \( b \). This phenomenon has been discussed in Fourier transform spectral interferometry, and a similar effect occurs in magnetic resonance imaging. Aliasing can be mitigated by passing the photodetector output through the noise equivalent bandwidth-limiting antialiasing filter (Fig. 4). Aliasing is a difficult problem to eliminate, because analog filters have finite impulse response transfer functions and, as such, cannot act as perfect brickwall filters with a cutoff frequency corresponding to the system noise equivalent bandwidth dictated by \( x_{\text{max}} \). Doubling the scan depth through by resolving complex conjugate ambiguity reduces the likelihood of aliasing. Oversampling and subsequent processing with an infinite impulse response digital filter is another potential solution.

5 Conclusions

We present a swept source OCT system with an all-fiber, turnkey swept laser source. We demonstrate a novel optoelectronic wavenumber linearization technique that yielded a near-transform-limited point spread function performance over the entire scan range, which had not previously been convincingly demonstrated with either Fourier domain or swept source OCT. We obtained excellent in-vivo images of the human cornea and anterior segment, and are currently scaling this system into the kilohertz regime for real-time imaging.
